ABSTRACT

With the advent of the automobile era, the accident occurring due to the human negligence and vehicle malfunction emerged as a potential threat to our loved ones. Due to high speed cornering, rollover accidents take place. To minimize such accidents, a new economical device that can be used to reduce vehicle vulnerability to rollover is high speed cornering assist device.

The high speed cornering assist device shall search as an altering device for the driver. If these signal lies in the zone to trip the vehicle, the driver shall be altered, so that driver could take the necessary action to prevent the rollover. The device consist of simple mass and spring system whose motion about mean position is monitored by proximity sensor which actuate to an alarming device hence to alert the drivers to take necessary measure to control their vehicle to avoid accidents.

Keywords: *Cornering, High Speed, Safety, and Rollover.*

I. INTRODUCTION

Now-a-days, accidents due to rollover are fatal and are increasing at a high pace. To minimize such accidents, a new economical device that can be used to reduce vehicle vulnerability to rollover is high speed cornering assist device.

The device is named as high speed cornering assist (HSCA) and it shall serve as an alerting device for the driver. The device will measure the angle of inclination of vehicle while cornering and transduce these measurements into the electrical signals to actuate a buzzer. If these signal lies in the risk zone that might lead to tripping of the vehicle, the driver will be alerted, so that he can take the necessary actions to prevent the rollover. The device is made intelligent by incorporating "switch off" action that will be initiated at the starting of the high risk zone. Under such circumstances the device will cut the engine supply so that the vehicle is retarded.

The inspiration behind this research is lack of economical devices available for heavily loaded automobiles like trucks, wagon, Lorries etc. Number of accidents has occurred in which the HGVs have rolled over as the driver wasn't aware of the tilt of the vehicle and hence lost control. The available devices are rare and expensive as they modify the suspension system to facilitate the braking action or it may vary the engine output regulating the brakes. Hence the need of an economical device was greatly felt that could prevent these types of accidents

caused due to tripping at the corner. In 1997, Yoshimi Furukawa and Mastao Abe also emphasized that there is a need to further propose control laws based on deeper observation and understanding on the tire and vehicle dynamics so as to ensure safety [1].

The device being proposed can be a part of any vehicle running on road, as its installation doesn't need any factory modifications. It also doesn't alter any other system nor voids the warranty of the vehicle. The device is cost effective as it can either work on the simple principle of potentiometer or on a proximity sensor. The device consist of simple mass and spring system whose motion about mean position is transduced either by a proximity sensor or by variably conductive devices, which actuates an alarming device which alerts the driver.

II. LITERATURE REVIEW

According to NHTSA (National Highway Traffic Safety Administration, US), more than 280,000 rollover accidents each year & out of these 16% are fatal and leads to death of our loved once [2] (*Figure 1*).

Figure 1. Fatal Rollover Accidents

A vehicle roll over is among the worst things that can happen on road. The chance for a rollover are more in taller and narrower vehicle having high center of gravity like the SUVs, pickups, vans and trucks etc. [3]. A rollover is a type of vehicle accident in which a vehicle tips over onto its side or roof, the lateral forces increase with speed and also with rapid change of direction as when driver makes too sharp a turn one way and over corrects the other one (*Figure 2*). A single-vehicle rollover is usually not caused by a steering maneuver. Instead the vehicle usually has to "trip" on something such as when its swerves into curb, potholes, or soft roadside shoulder. The government has estimated 95 percent of rollover results from trips. As the number of accidents increases, so is the concern for the safety of passenger leading towards the invention of devices which can prevent rollover and assist the driver. The technologies available are expensive and works on the suspension system actuates the brakes to slow down. Studies suggest that electronic stability control systems can reduce the

chances of fatal injuries by 35% [4]. In 2002, Aleksander Hac suggested a simple yet insightful model to predict vehicle propensity to rollover is proposed, which includes the effects of suspension and tire compliance [5].

Figure 2. Location of Roll Center in Vehicle

Technologies available in nowadays vehicle are as follows.

- Cornering brake control

Cornering brake control or CBC is an automotive safety system introduced by car makers like BMW and MERCEDES BENZ (ESP Dynamic Cornering Assist and Curve Dynamic Assist). It is a further development and expansion of the anti-lock braking system, designed to distribute braking force during braking whilst cornering.

- Active trace control

The Active Trace Control is a control system which can apply braking automatically to each wheel, helping to keep the vehicle on the cornering line as steered. The system helps drivers smoothly maintain control, so they are able to relax and drive around corners more confidently.

- Vehicle stability assist

The Vehicle Stability Assist (VSA) was introduced by Honda to its vehicles in 1997. The term is Honda's version of Electronic Stability Control (ESC), an active safety feature developed to correct oversteer and understeer by using several sensors to detect loss of steering control and traction while simultaneously braking individual wheels to help the vehicle regain stability.

III. OBJECTIVE

The High speed cornering assist is designed with the following objectives:

- To prevent the increasing number of accidents due to rollover.
- Simple and effective design alerting the driver in the position of roll over.
- High sensitivity

- Economical
- Can be installed easily into any vehicle

IV. METHODOLOGY

As the vehicle takes a sharp turn, there is possibility that the vehicle will rollover, this happens because the forces acting on it undergo significant variation. The driver also feels these forces when a vehicle turns around a corner. These forces result in the tilting of the driver as well as the car, the above concept is based on the “Newton first of motion” which defines the term “inertia”. In order to study the cornering scenario all the forces are considered, acting on the vehicle while undergoing a turn.

On a turn, as the vehicle moves the automobile body and its suspension system tilt's a little to attain the stability. This case is similar to the banking of road in which the vehicle is kept uniform throughout and the tilt or inclination is provided on to the roads which prevents the slipping and rollover of vehicle while taking a turn. The centrifugal force acts outwards from the vehicle whereas the friction force acts towards the center of curvature of the curve road and a balance between these two forces help to keep the vehicle stable on the road. In this the roads remain flat but due to turning the suspension inclined at an angle so that the grip on the road remains constant. So this inclination of suspension can be calculated by the formula given by the NHTSA (National Highway Traffic Safety Administration, US). After the determination of this angle, the body can be assumed to be inclined at this angle and further all the forces acting on it can be realized.

To calculate these forces, considered a quasi static rigid body inclined at an angle referred above. Then the basics of “Newton equations of motion” are woven with the vehicle dynamics and with the concept of rollover including the behavior of forces on banking of roads to obtain the necessary characteristic values.

The calculations are made with respect to the center of gravity (COG), and all the forces are assumed to be acting on it. Further the motion of the central mass, placed in our device is studied along the longitudinal axis. This motion then forms the basis of the scale of the proposed device and the necessary configuration of the proximity sensors or the variably conductive plates. In addition to this we tried to find the necessary placement position.

V. DESIGN

The device consist of a central mass connected to spring on both the sides, this arrangement is enclosed in a casing facilitating motion along the longitudinal axis only. The surface of casing is aluminum metal upon which the mass can slides to and fro. The plate has a friction lining so that any random motion of mass about the mean position can be arrested and result is steady values rather that varying with time and conditions (*Figure 3*).

Figure 3. Proposed Design of Device

There are two ways of transducing the motion of the central mass, the first being the conventional variably conductive plates, that transfer current depending upon the resistance of the contact region. In the other way, two proximity sensors can be placed upon the vertical surfaces of the mass. These sensors shall measure the distance from the fixed ends. In both the cases a suitable amount of insulated zone or parameters are kept that help us in differentiating between the risk zones.

The device design is unique and can be installed in any vehicle and is needed to be placed inside the passenger compartments above the center of gravity, so it is required to be concise and light. The position of device determine the spring constant and the critical angle of rollover is also height dependent, so every device should be calibrated for specific vehicles independently.

VI. CALCULATIONS

The force acting on the automobile will taking a turn is considered in which the centrifugal force away from the center of curve of the curved road and the friction force acts towards this center.

6.1 Assumption to be made for calculations

- The forces are assumed are for a quassi static rigid body.
- The vehicle travels with a uniform speed of 60 Kmph.
- The vehicle takes a 90 degree turn.
- The radius of the turn is 18 m ($r_1 + r_2 = R$) (Figure 4).

Figure 4.Path While Cornering

Critical angle of inclination while cornering after which rollover occurs (θ_{max})

$$\theta_{max} = \tan^{-1} \left(\frac{T}{2H} \right) \text{ (Figure 5, 6)}$$

Figure 5.Force Due to Lateral Acceleration

Figure 6. Inclination of Vehicle

As per the above formula [2], critical angle of rollover is found out for a Honda civic car, a minivan and a truck. For each of the critical angle, a safe designing angle is selected to maintain the necessary factor of safety (*Table 1*).

Table 1. Critical and Designed Angles for Various Vehicles

Vehicle Type	Critical Angle of rollover	Designing Angle
Honda Civic	48.5599°	35°
Mini Van	41.98°	30°
Truck	34.364°	25°

The selection of a designing angle is based upon two factors, the first being the safe zone limit given by the lateral acceleration vs. rollover angle and the second being the mass of that a vehicle carries under maximum load. So for the assumed values the graph for lateral acceleration vs. rollover angle in *Figure 7*

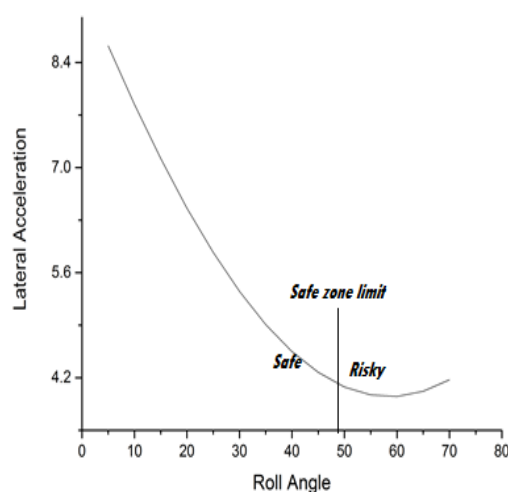

Figure 7. Variation in Lateral Acceleration with Roll Angle

The calculation for force acting on the central mass of the device:

Resultant forces on vehicle in Figure 8.

Figure 8. Resultant forces on vehicle

Acceleration of the mass block

$$a = \frac{F}{M} = \frac{v^2}{r} - \mu g \cos \theta - g \sin \theta$$

✧ a = acceleration, F = force, M = mass, v = velocity of vehicle, μ = friction coefficient, g = acceleration of gravity, θ = angle of inclination

Time elapsed during turn

$$t = R\theta / v$$

✧ t = time taken to take a turn, R = radius of curvature of road, v = velocity of vehicle

Velocity which with mass slides

$$v = u + at$$

✧ v = velocity with which the central mass slides

Distance moved by Mass

$$s = \frac{v^2 - u^2}{2a}$$

✧ s = the displacement of mass along the longitudinal axis

Spring needed to get this displacement to 6.5 cm

Table 2 – Results

Name	Angle (Degree)	Acceleration of central mass (m/sec ²)	Velocity with the mass slides (m/sec)	Distance moved by the central mass (m)
Civic	35	4.9096	8.3230	7.05487
Mini Van	30	5.35089	9.0711	7.68898
Truck	25	5.868951	9.9494	8.43341

Sensitivity of the device

Sensitivity of the device is the ratio between the changes in the output of a device to the corresponding change in the measured variable. For a good device or process, the sensitivity should always be high, thus producing higher output amplitudes.

For a quassi static body, under consideration the variation in distance travelled by the central mass per unit change in the angle of inclination gives the sensitivity. The variation is shown as below.

$$\frac{\Delta X}{\Delta \theta} = \frac{X_{n+1} - X_n}{\theta_{n+1} - \theta_n}$$

(a) Sensitivity graph

Variation in Sensitivity with respect to θ is shown in Figure 9.

Figure 9. Variation in Sensitivity with respect to θ

(b) Conclusions from the graph

1. The change in displacement of central mass is negative and turns to positive when the angle is very high.
2. For the given value of $\theta = 30^\circ$, used for the design, the change in displacement will always be negative.

Negative change implies that the displacement for a 5° change is more than for a 10° change.

Following outcomes from the graph will force to introduce time delays in the device, so that the buzzer gets activated at a particular time only. Hence, providing a high sensitivity range to the device.

Position Related Adjustments needed

Currently the device is assumed to be kept at the Center of Gravity (COG), but practically it can't be placed over there so it will result in the variation θ_{\max} and all the variables. The variation of Height vs. Angle of Inclination is shown in *Figure 10*.

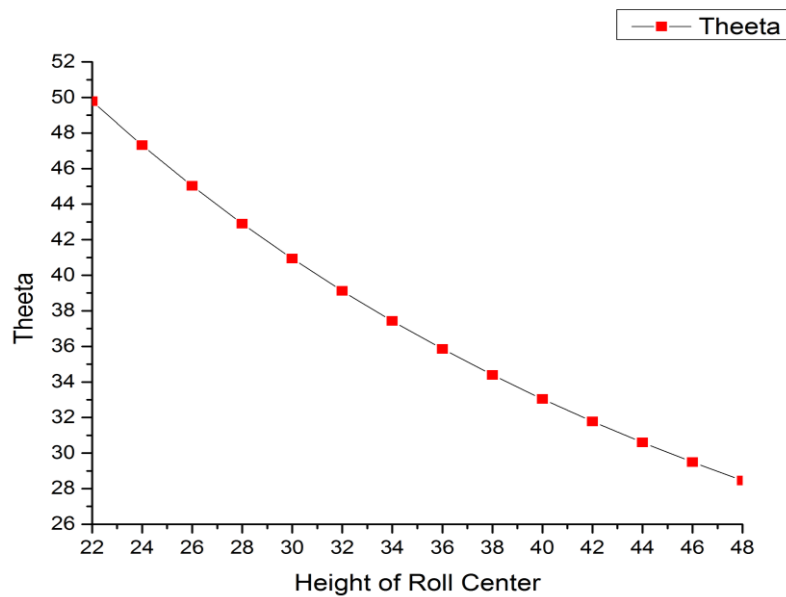

Figure 10. Variation in θ with change in Height of roll center

As we increase the height of placement, the critical angle will reduce correspondingly. Hence the device should be placed and calibrated for to the Maximum height obtainable by the chassis.

VII. RESULT & FUTURE SCOPE

The device shall serve its rightful purpose and can be used for any vehicle, given the condition that it is calibrated for the vehicle's maximum load and as per the height of placement. The proposed device has a non-linear negative scaling i.e. the least value is present at the end of the scale. The springs used provides the smooth movement of the central mass, hence result in accurate operation. Further this is just the start towards a greater goal of producing low cost, efficient devices that could be implanted in vehicles that help in saving vehicles from potential accidents. Moreover further research can be conducted to make the device linear and make it more efficient. The proposed design of the device's casing is in *Figure 11*.
